The NAIRU in Israel: an Unobserved Components Approach^{*}

Tanya Suchoy and Amit Friedman

September 2002

Abstract

The Non Accelerating Intation Rate of Unemployment (NAIRU) is estimated for the post-stabilization period, as an unobserved stochastic variable, using state-of-the-art State Space Models. The NAIRU is identi-...ed by a Phillips curve equation, and is assumed to follow a random walk. The basic model is augmented by an equation that captures the persistence of the unemployment gap. We also use the joint system that was ...rst introduced by Apel and Jansson (1999) in order to estimate potential output and the NAIRU simultaneously. Con...dence intervals around the NAIRU were computed by jackknife technique. The results indicate that the actual variation of unemployment has only a minor exect on the NAIRU, which remained relatively stable throughout the sample period. The state variables have su¢ciently stable characteristics to be successfully predicted, at least one step ahead. However, policy implications that may be derived are sometimes limited, as the uncertainty around the estimated NAIRU is substantial. No evidence for hysteresis were found. The estimates show that the disintation process during the 1990s did not cause an increase in the NAIRU.

Key words: NAIRU, Phillips curve, output gap, Kalman ...Iter, SUR equations, jackknife technique.

[&]quot;We thank R.D.Porter, Z. Hercowitzs and R. Melnick for discussion, Y.Rubinstein for constructive comments, and R. Alsheikh for helping us with the SAS programming.

1 Introduction

Unemployment in Israel varied substantially during the 1990s. This was the result of both the business cycle and a huge immigration in‡ux during the ...rst years of the decade, as well as other structural changes. During that era, the Bank of Israel followed a descending in‡ation target regime. These changes suggest that some of the basic properties of the economy have changed as well.

The perception that some fundamentals of the economy lie underneath the business cycle "veil" is one of the major concepts of economic thought. While some of these fundamentals are backed up and well de...ned by theoretical models, empirical work that aims to "recover" these forces has encountered substantial obstacles.

The major source for these obstacles is that some of them are unobserved: they are blurred due to numerous shocks that cause deviations from long run equilibria. Hence the economy is constantly moving in the neighborhood of these fundamentals, but the complexity of the economy and the realization of new shocks does not allow for exact identi...cation.

Among these "obscured" fundamentals, the natural rate of unemployment has played a key role for decades. The interest in this variable is twofold: ...rst, to investigate the factors that are responsible for its changes (e.g. labour market structure, demography). Second, to derive policy implications, especially in the context of the unemployment in‡ation trade-o¤. When using the terminology "natural rate" it is essential to de...ne in what sense this rate is "natural": economic theory nowadays generates more than one de...nition (see Rogerson (1997)). One of these de...nitions, and the focus for this work, is the Non Accelerating In‡ation Rate of Unemployment (we use its acronym NAIRU, hereafter). As its name suggests, the NAIRU is the unemployment rate that is consistent with a stable in‡ationary process, in the absence of supply shocks, or simply the rate of unemployment that does not press the price level. A comprehensive theoretical and empirical review of the NAIRU framework was presented in a special issue of the Journal of Economic Perspectives (1997).

Knowledge about the NAIRU may have important policy implications, since it provides a better understanding of in‡ationary pressure, especially the in‡uence of real factors such as the unemployment gap on in‡ation. The simple, not to say simplistic way of thinking about the NAIRU is to assume it has a ...xed rate over time: on that account, the "textbook NAIRU" in the US was long quoted to be 6 percent (see Blanchard (1997)). Recent business cycle episodes in some OECD markets disprove the ...xed NAIRU assumption. For instance, unemployment went to historically low levels both in the UK and US during 2000, without any visible in‡ationary pressure, which may be interpreted as a decline in the NAIRU. In the US, where 6% NAIRU was commonly held, unemployment went down to 4% with only minor signs of pressure on wage or price in‡ation. As for Israel, evidence for changing NAIRU during the poststabilization era has been found by Yotav-Solberg (1997), and Sussman and Lavi (1999), who suggested that an I(1) process is reasonable.

There are several possible estimation strategies for identifying the NAIRU.

The classic way is to construct a price-price equation where the level of unemployment a^xects intation. Using some restrictions on the intation process that ensure that it is stable, it is possible to use the estimated coe¢cients in order to generate the NAIRU. This framework was used by Yotav-Solberg (1997), who found that even when restrictions on the intationary process are imposed, the generated NAIRU tends to move much more than one would think of as reasonable. The solution to this problem usually used in these models is to smooth the estimated NAIRU till a "reasonable" NAIRU volatility is achieved. In countries with stable intation rates, this framework seems to work better (see Tulip (2001)).

The present study uses the unobserved components (UC) approach. The essence of this approach is to treat the fundamentals, namely the NAIRU, the unemployment gap, and potential output as latent variables. Assumptions regarding the stochastic processes that describe the evolution of these latent variables over time, enable their exact identi...cation. This approach retects the fact that not much is known about the factors that determine them (Apel and Jansson (1999), AJ hereafter). Since the determinants are unknown, they are treated as random. The unobserved variables are "recovered" through a set of identifying equations that de...ne the relation between these variables and observed variables. The identifying equations may be structural in the sense that they have some theoretic grounds or, alternatively, identities that generate statistical decompositions of actual data to these variables.

In order to estimate the NAIRU one has to have a well speci...ed intation process. Following Gordon (1997) this study uses a variant of the "triangle" version of the Phillips curve, where the intation process depends on three factors: inertia, demand and supply. The basic framework is extended by specifying the unemployment gap as an AR process: this ...ts Friedman's concept that deviations from the natural rate can not be permanent (see Laubach (2001)). This framework is extended further in order to simultaneously estimate the NAIRU and potential output (see AJ (1999)).

The UC approach has been used extensively in recent years. Statistical decompositions of GDP were presented in Harvey (1989). Phillips curve based estimates for the NAIRU were presented by Gordon (1997), and recently by Laubach (2001) A joint system for NAIRUnOutput gap estimation was ...rst introduced by AJ (1999). This system serves nowadays as the IMF "workhorse", and was also estimated for Israel (Bal-Gündüz (2001)).

This study uses di¤erent State Space Models in order to estimate the NAIRU. An iterative procedure was adopted, involving at each step Kalman ...Iter and SUR equation routines, that sequentially improve the model parameters and expected values of latent (state) variables according to Maximum Likelihood criteria.

The results indicate that the NAIRU is surprisingly stable. Changes in the actual unemployment rate have only a minor exect on the level of the NAIRU. The estimated potential output varies signi...cantly, suggesting that the immigration in‡ux had an important role. In order to build con...dence interval for the NAIRU we applied the jackknife technique. As in Laubach (2001) the uncer-

tainty around the NAIRU and potential output estimates is substantial. During the investigated period, however, the unemployment rate di¤ered signi...cantly from the NAIRU in three episodes - as for example during the business boom of 1995-96.

2 The model

2.1 NAIRU as unobserved component

We follow previous works that were quoted before, and use a Phillips curve speci...cation in order to de...ne the NAIRU. We use a variant of the expectations augmented Phillips curve presented by Friedman and Phelps, which emphasized that the intation-unemployment trade-o^x does not exist in the long run.

where \mathcal{U}_t is the in‡ation rate, \mathcal{U}_t^e is the expected rate, u_t is the unemployment rate and u_t^n is the NAIRU. Since expected in‡ation is in Israel is highly adaptive, i.e. $\mathcal{U}_t^e = \mathcal{U}_{t_1} \mathbf{1}^1$, we estimate this relation using the …rst di¤erence of in‡ation.

Note that the causality in this speci...cation is somewhat counter-intuitive. Usually, we think of the unemployment-in‡ation trade o¤ as the ability to boost real activity by an unexpected price shock. This speci...cation ignores this feed-back channel. Instead, the unemployment gap is used as an explanatory variable - a proxy for excess demand. As explained by Gordon (1997) one can justify this handling by empirical ...ndings that suggest that unemployment Granger-cause in‡ation (see King and Watson (1994)).

Speci...cally, we use the so-called "Gordon's triangle" equation. The general structure of the triangle is:

where intation is a function of three factors: inertia, demand and supply. The excess demand is captured by the unemployment gap, while the x's capture supply shocks. This equation implies that when unemployment persists under a certain "natural" level, other things equal, the intation rate will rise. This "natural" level is the NAIRU. The NAIRU is well de...ned in this context if and only if the sum of the lagged intation coe¢cients equals 1.

This formulation assumes that in the absence of supply shocks, and if actual unemployment equals the NAIRU, the intation rate converges to a constant, long-run equilibrium level. This assumption does not match the intation trend during the estimated period (1990s), due to the descending intation target regime that was implemented (successfully) at that time. Hence, we estimated the model in ...rst di¤erences of intation.

¹Note that under rational expectations the this speci...cation is reduced to a contemporaneous relation between the unemployment gap and unexpected intation, as expected intation incorporates all the information up to time t. Thus, lagged unemploment gaps can not explain unexpected intation.

This speci...cation does not assume an implicit long-run equilibrium (Bal-Gündüz (2001)), and therefore is more appropriate in the case of Israel, and still, de...nes a meaningful NAIRU (see AJ (1999)). An alternative speci...cation may use the unexpected intation, namely the dimerence between actual and expected intation. In the case of adaptive expectations, the two dimerent speci...cations resemble each other.

The ...rst term in the triangle is the inertia term that is captured by lags of the dependent variable. An alternative speci...cation that we use is a moving average speci...cation:

The justi...cation for this speci...cation is empirical: the equations are not equivalent, even if the AR process is invertible, since other components remain unchanged. However, the residuals that are generated by the di¤erent models suggest that this speci...cation captures inertia as well.

The atheoretical part of the model speci...es the stochastic process of the NAIRU and the unemployment gap. We now turn to complete the system with some assumptions about the dynamics of the unobserved components. Equation (6) speci...es the NAIRU process as a random walk. Although in the long run one would not expect the NAIRU to follow a random walk process since it is bounded², this process seems to be a good approximation for short-run movements. As cited in the introduction, evidence for an I(1) speci...cation was found by Sussman and Lavi (2001).

Together, the system is composed of equations $(5) - (7)^3$: The theoretical part of the model is captured by a triangle relationship (the measurement eq. (5), whilst the atheoretical part of the model speci...es the stochastic process of the NAIRU and the unemployment gap (transition eq. (6)-(7)).

$$u_{t}^{n} = u_{t_{i} 1}^{n} + {}^{"n}_{t}$$
(6)

$$(u_{t i} u_{t}^{n}) = \pm_{1}(u_{t i} | i u_{t i}^{n}) + \pm_{2}(u_{t i} | 2 | i u_{t i}^{n}) + {}^{"gap}_{t}$$
(7)

A parsimonious version, composed of equations (5) - (6) only, is the speci...cation used by Gordon (1997). As we describe later, this speci...cation tends to generate a volatile NAIRU, unless a restriction is imposed on " $_{\rm t}^{\rm n}$. In the extreme case the volatility is restricted to zero and the NAIRU is ...xed: in other

² Note that in a symmetric random walk process the probability that the random variable will sooner or later (and therefore, in...nitely many times), return to its initial position, is one. (for univariate and bivariate variables, see Feller (1957)).

 $^{^3}$ Actually, the system is closed by an additional equation, an identity that restricts the sum of unobserved components to be equal to actual unemployment, imposing the decomposition to be consistent (see appendix B).

cases, an assumption of the smoothness of the NAIRU is required. As a result, the smoothness of the NAIRU achieved by this speci...cation is an assumption rather than a result. In order to avoid this di¢culty, an augmented system with eq. (7) was constructed. This speci...cation requires that the unemployment gap follows an auto-regressive process. Note that the AR parameters are estimated simultaneously without restrictions. Hence, the process is not restricted to be stationary. The augmented system generates a relatively stable NAIRU as a result, without any further direct restrictions. Moreover, the estimated ±'s suggest that the unemployment gap is stationary, although the results of an ADF test applied on the estimated series are inconclusive.

This equation has some economic reasoning since "sticky" labor markets cause inertia in the unemployment gap. It also imposes an indirect restriction on the NAIRU process, thus, no additional direct assumptions on the NAIRU volatility are required in order to get a relatively smooth NAIRU path.

2.2 Potential output as unobserved component

The system below generates a pure statistical decomposition of actual output. The measurement equation is an identity (with no error term) that de...nes actual output as a sum of two components: potential output and the output gap. The transition block that is composed of equations (9) and (10) de...nes the stochastic properties of the unobservables. Potential output is assumed to follow a random walk plus drift process (9), while the output gap is assumed to be an AR(2) process (10). This captures the persistence of the business cycle. This system was also estimated by de Brouwer (1998). Likewise, an AR(2) process was estimated, with no further restrictions on the residuals.

$$y_t = y_t^p + y_t^{og} \tag{8}$$

$$y_t^p = y_{t_i 1}^p + d + {}^{"p}_t$$
 (9)

$$y_{t}^{og} = '_{1}y_{t_{i}1}^{og} + '_{2}y_{t_{i}2}^{og} + "_{t}^{og}$$
(10)

The estimated parameters (' $_1 = 0.59$; ' $_2 = 0.19$) indicate that the output gap is stationary. Hence, the system decomposes actual output into a stationary and a non-stationary process⁴. This means that the shocks to potential output are permanent, while the shocks to the gap process are transitory (see Yachin and Menashe (2001)).

2.3 Simultaneous system for NAIRU and Potential Output

As ...rst introduced by AJ (1999), it is possible to simultaneously estimate the NAIRU (and therefore the unemployment gap) and potential output (and the derived output gap). This section describes this augmented model.

 $^{^4}$ This decomposition is not unique, though. It is possible to decompose output into two non-stationary processes: this depends on the initial values of the ½'s.

The term "potential output" is in a way inde...nite, and mirrors the equivocal nature of the term "natural rate". A thorough review of this issue has been presented recently by Yachin and Menashe (2001). As for the output gap estimated here, it is simply a "NAIRU output gap", meaning that potential output in this study is the level of output that does not cause in‡ationary pressure.

The system ties the NAIRU and potential output by augmenting the measurement block using Okun's law (eq. 12), that relates cyclical unemployment to cyclical output. Since a new unobserved variable is added, an additional assumption about its dynamics is required. Consequently, the system is completed by augmenting the state block with an equation that describes potential output dynamics as a random walk plus drift (eq. 15). The drift captures the growth of the labor force as well as improvements in productivity.

$$\mathfrak{P}_{4t} = \ \mathbb{R}(L) \ \mathfrak{P}_{4t} + \ \mathbb{M}(L) (u_{t \ i} \ u_{t}^{n}) + \ \overline{x}_{t} + \ \mathbb{M}_{t}^{\mathfrak{P}_{4t}}$$
(11)

$$y_{t} = y_{t}^{p} + {}^{\circ}_{1}(u_{t} i u_{t}^{n}) + {}^{\circ}_{2}(u_{t} i i u_{t}^{n}) + {}^{"y}_{t}$$
(12)

$$u_t^n = u_{t_i 1}^n + {}^{"n}_t$$
(13)

$$(u_{t i} \ u_{t}^{n}) = \pm_{1}(u_{t i} \ _{1 i} \ u_{t i}^{n}) + \pm_{2}(u_{t i} \ _{2 i} \ u_{t i}^{n} \ _{2}) + "_{t}^{gap}$$
(14)

$$y_t^p = y_{t_i 1}^p + d_t + {}^{"p}_t$$
(15)

3 Estimation technique

In order to estimate the system parameters we ...rst cast it in a State-Space Form (SSF). The essence of this representation is to express a dynamic system with two equations (or, in the multivariate case, by two blocks of equations written in a matrix form):

The measurement equation describes the dependence of observed components (such as in‡ation and output) on a set of variables, some of which may be unobserved (state variables), and others observed "regular" (exogenous) variables. This block may be based on theoretical grounds (hence, "structural"), or on identities (this will be clari...ed in the next sections).

$$Y_{t} = H_{n \le m} Z_{t} + B_{k \le 1} X_{t} + y_{t}$$
(16)

where Y_t is a vector of n response (dependent) observed variables at (and up to) time t,

 Z_t - vector of m unobserved (state) components at time t,

H - measurement matrix, assumed to be time invariant,

 X_t - vector of k exogenous or lagged dependent variables with <code>coetcient</code> matrix B,

 $*_t$ - vector of serially uncorrelated disturbances with $\mathsf{E}(*_t)=0$ and V ar(*_t) = R.

The transition equation, describes the evolution of the unobserved components over time, i.e. the transmission from observation t_i 1 to t. The transition

equation is based on a set of atheoretical assumptions, retecting the fact that our knowledge about the factors that determine their evolution is limited (AJ, (1999)). These assumptions are based on some economic grounds, or may be justi...ed empirically, such as the evaluation of potential output as a random walk plus drift.

The transition equation describes the dynamic process of the unobserved components Z_t , and takes the form of a ...rst order Markov process:

$$Z_{t} = F_{m \in m} Z_{t_{i} 1} + \hat{t}_{t}$$
(17)

where F - is an m £ m transition matrix, assumed to be time-invariant,

 \hat{f}_t - vector of serially uncorrelated disturbances with E($\hat{f}_t)$ = 0 and V ar($\hat{f}_t)$ = V:

For example, the SSF for the system of equations (11-16) is given below (a full set of SSF's for the dimerent models used throughout this work is given in the appendix B) 2 3

The aim is to obtain expected values of the state components Z_t^1 ;:: Z_t^m (t = 1;::T) and of their variances, as well as measurement and transition coe¢cients.

Note that had Z^1 ; :: Z^m been observed, the matrices H and F would have been immediately evaluated by straightforward regression estimates. On the other hand, if the system matrices H; F; R and V were known, the unobserved components Z_t^1 ; :: Z_t^m would be calculated by one pass of the Kalman ...Iter (a full description of the Kalman ...Iter and smoother is given in appendix C).

In order to solve this dual estimation problem, we apply the Estimation Maximisation (EM) algorithm of Watson and Engle (1983). This is a derivative

free, iterative algorithm that consists of a Kalman ...Iter pass and SUR estimation. The idea of this method is to maximise the expected likelihood function, by improving the set of unknown parameters and state variables, using information only on their ...rst two moments. This means that the likelihood function maximisation is achieved not through its derivatives but step by step, indirectly.

The likelihood function L of the unknown parameters in (16) and (17) depends on the innovations $Y_{t,i} \in (Y_t j Y_{t_{i-1}}; ...; Y_1; X_t; ...; X_1)$ and their variance C_t :

$$L(\mu) = \frac{1}{2} \frac{\mathbf{X}}{t=1} \log jC_{t}j_{i} \frac{1}{2} \mathbf{X} (Y_{t i} H Z_{t j t_{i} 1 i} B X_{t})C_{t}^{i} (Y_{t i} H Z_{t j t_{i} 1 i} B X_{t})^{0}$$

where μ is the vector of unknown parameters.

The innovations and their variances are calculated previously by a Kalman ... Iter pass.

When the best parameter values are obtained, a new pass of Kalman …lter is run, generating an "improved" set of state variables Z^1 ; :: Z^m and their variances. This is the "estimation" step of the algorithm, while the …rst step was "maximisation".

More precisely, the estimation starts with the initial matrices H; F; R; V and initial values for the mean and variance of the state variables. It allows the ...rst pass of the Kalman ...Iter, generating Z¹; ::Z^m, by one-step prediction, i.e. Z_{tjt_1} . While the system (16)-(17) holds for conditional expected values of Z_t , the last can be evaluated using the smoothing procedure that recursively calculates $Z_{tjT} = E(Z_{tj}Y_T; Y_{T_i 1}; :::; Y_1; X_T; X_{T_i 1}; :::; X_1)$ and their mean square error matrices $P_{tjT} = var(Z_{tj}Y_T; Y_{T_i 1}; :::; Y_1; X_T; X_{T_i 1}; :::; X_1)$. The values Z_{tjT} are the best estimates for expected values of Z_t given the information available till T, and the parameter set μ . The smoother runs backward from the last to the ...rst observation of each Z variable.

Once the Z's are generated, they may be considered as "regular", observed variables. Next, the maximisation step can be carried out. When the system is unrestricted, ordinary least square estimates are $su \ cient$, that is :

where Z consists of smoothed state variables Z_{tjT}^1 ; ::: Z_{tjT}^m (t = 1; ::T) and Z_{t-1}^1 - of their lagged values.

In our case the system contains parameter restrictions, such as zeros and ones in H and F matrices. Some equations of our system are fully restricted, having no degrees of freedom, so OLS estimates for these equations cannot be obtained.

Assuming that residuals among partially restricted and not restricted equations may be correlated, at each iteration we solve a reduced SUR system, which includes only full rank equations.

In other words, having n + m equations of which I are fully restricted, we compose at each iteration a SUR system of $n + m_i$ I equations and obtain

"reduced" matrices H^* ; F^* and B^* . To complete this step, we need only to enlarge the system, by resubstituting the 0's and 1's at their original positions.

When the parameters of H; F and B are updated and a new series of residuals \ast_t and $\hat{}_t$ are available, together with their variance matrices R and V , we can switch to the next pass of the Kalman ...Iter, constructing an "improved" set of Z's.

Therefore, one iteration of the EM algorithm involves solving SUR equations (maximisation step), one pass of the Kalman ...Iter, which calculates one-step predictions of state variables and one pass of the Kalman smoother that evaluates their conditional expected values (estimation step).

The process converges when the relative changes of parameters, likelihood function, and state variables become negligible.

Our experience shows that this method is sensitive to some initial values, while to some of them it is rather indi¤erent. For instance, we found that even when the guesses about mean Z values are very poor (even zero vector was tried) we reached convergence near the same region. The sensitivity to initial values of the transition matrix F and measurement matrix H (that were based on ad-hoc considerations) is low, too.

Residual variances (R and V initial matrices) depend also on the initial assumptions about B coeCients, the intuence of the exogenous variables on the response. They were approximated by OLS, assuming the NAIRU was ...xed over time and equal to the sample average.

The algorithm tends to be quite sensitive to the initial Z's variance, however, the solution to this problem was to use a di¤use prior (see Harvey, 1989): this method calculates the initial variances under lack of stationarity, assuming the variance to be in...nite. The results support this treatment, as some of the eigenvalues of F are near unity. Alternatively, we tried to enlarge the variances till convergence was reached: this method was inferior to the previous one in terms of convergence speed. The reason for this di¤erence is that we do not have a good guess for the relative variance of the state variables.

4 Empirical results

Three main models were used: the ...rst version (V1, hereafter) is the basic form, composed of eq. (5) and (6), without unemployment gap as a state variable. The second model specimes the unemployment gap as an AR process (eq. (5)-(7)) and the third model is the AJ model (V2 and V3 respectively). This order is not random: each model is in fact a nested parsimonious form of the next model. In addition, statistical decompositions of output are presented.

This section describes the estimation results of the models, and is organized as follows. First we give a short description of the data. Than, we discuss the results for two partial models for the NAIRU, and then switch to the joint NAIRU/Output model results. We also compare the model parameters obtained from the di¤erent versions.

The data are composed of quarterly data between 1987:1 till 2001:1. Since the model assumes that intation process is at least partially dominated by real factors, the sample period includes only the post stabilization period. Before that, it is clear that the process was almost completely dominated by nominal factors⁵ ¢¼ is the second di¤erence of seasonally adjusted log CPI ⁶. The unemployment rate is seasonally adjusted chained unemployment rate. Supply side shocks are captured by the relative price of imports excluding oil and diamonds, the relative price of oil, deviations of labor productivity from its trend and the relative contribution of new immigrants to population growth. Other variables that have been checked include the IMF's Real Exchange Rate⁷ (RER), and the interest rate. A complete description of the data is given in the data appendix (A).

Table 1 presents the results obtained by the dixerent models. Our model selection strategy was to choose a speci...cation for which the state space model performance was best in terms of stability, and to eliminate the exect of the unemployment gap on in tation. Thus, we "over-controlled" for this variable, and even insigni...cant lags of the unemployment gap are included, clearing also possible level exects, and not only change exects (see AJ (1999)). We, nevertheless, applied the "parsimony principle" when selecting the exogenous variables⁸. The models were estimated using two alternative speci...cations: an AR speci...cation, where inertia is captured by four lags of C_{4} , and a speci...cation where inertia is captured by two moving average terms. When using lagged variables of the dependent variable, they were treated as "regular" exogenous variables⁹.

⁵ Although Sussman and Lavi (1999) have found that even during the high in ‡ation period (1975-1985) real factors had signi...cant in tuence on intation.

⁶Both X12 and SABL procedures were applied. Major di¤erences between the seasonal adjusted series appeared during the ...rst two years of the sample. After 1989 the di¤erences are negligible.

⁷ Although this variable was used as a supply shock in several previous works, the Real Exchange Rate may be confounded by demand shocks.

⁸ An alternative strategy was used by AJ (1999), and by Bal Gunduz (2001) where the system includes 5 lags of all exogenous variables. Our treatment of inertia and the unemployment gap is identical, however. ⁹ For a justi...cation of this treatment see Hamilton (1994) or Harvey (1989). Alternatively,

Figure 1: System estimation results

The estimates, as presented in Table 1, are in accordance with economic theory. The sums of the coe¢cients of the unemployment gap in the Phillips curve equation (1/2 and 1/2) are negative for all speci...cations, as is the sum of the coef-...cient in Okun's law equation (in V3). The transition matrix coe¢cients imply that the unemployment gap process is stationary. There is a clear trade-o¤ between augmenting the system and the average standard errors of the unobserved components as calculated by the Kalman smoother¹⁰. The estimated error term variance of the NAIRU varies between 0.017 and 0.045. This interval, although shifted downward, overlaps with some of the restricted values in Gordon (1997), where a SD of 0.2 was used. Since the models were not selected on the basis of the levels of signi...cance of the explanatory variables, we present later single equations estimates that were constructed using standard considerations with the relevant t-statistics.

the lagged variables may be treated as state variables.

 $^{^{10}}$ The average SE's are calculated by averaging the diagonal elements of the $P_{t=T}$'s for t = 1::T (see appendix C)

Figure 2: Actual unemployment and the NAIRU

4.1 The NAIRU

The most noticeable result is the stable pattern of the NAIRU during the sample period. Although unemployment rate has varied from a peak of 11.3 % to a low of 5.8 %, the NAIRU during this period changed by no more than one percentage point, as shown in Figure 1¹¹. Note that this result holds for the models that were generated without any direct restrictions on the NAIRU variance (V2 and V3 below), con...rming the variance constraint in the ...rst model.

The second result is that the level of the NAIRU is quite high: in fact, in all the speci...cations, the average level of the NAIRU is higher, by 0.1 to 0.3 percentage points, than the average level of unemployment (8.39%). This result may retect the fact that during the ...rst years of the sample period, nominal factors still dominated the intation process¹².

The results from the di¤erent systems are given below. As presented in Figure 3, the NAIRU generated by the di¤erent systems resemble each other, though some di¤erences emerge. As claimed before, the smoothness of V1 is more an assumption than a result. The variance of the NAIRU in V1 was restricted so that its amplitude resembles that of the unrestricted V2. Although

 $^{^{11}}$ V1 was generated by the assumption that the NAIRU follows a random walk only. V2 is a model where an additional assumption was made on the process of the gap (AR(2)). V3 is the augmented AJ model that includes output.

 $^{^{12}}$ As shown by Sussman and Lavi (2001), money growth (or alternatively, monetary policy as retected by the real interest rate) dominated the intation process during the ...rst years of the sample.

Figure 3: NAIRU comparison

the pattern is similar, V1 generates smoother a NAIRU. The "edgy" pattern of V2 is the result of the decomposition of the unemployment rate into two di¤erent components, where the second component (the unemployment gap) is generated by an AR(2) process.

"Digging Deeper" At ...rst sight, the NAIRU estimates, especially V1, look as if they could have been generated by a univariate ...Iter such as the HP ...Iter. A closer look at the results shows that these series di¤er substantially. The ...rst obvious di¤erence is the series average: while the HP ...Itered series has the same average as the original series, the generated NAIRU series is above average. As presented also by Yachin and Menashe (2001), it is interesting to check the correlations between the computed series and an HP ...Itered series. Table 2 shows that the HP series is highly correlated with the original unemployment series while the state space NAIRU estimates are less correlated. Not surprisingly, the correlation coe⊄cient drops as the system includes a larger information set. Hence when the NAIRU is constructed using in‡ation and unemployment only, the correlation coe⊄cient is still high (but still below the univariate HP ...Iter). When using the assumption that the unemployment gap follows an AR process the coe⊄cient drops to 0.66 : and when introducing output the coe⊄cient drops further to 0.64.

Table 2: Correlations between state space NAIRU							
estimates and HPItered unemployment							
	U_hp	U	V1	V2_MA	V3	V2_AR	
U_hp	1.00						
U	0.90	1.00					
V1	0.82	0.83	1.00				
V2_MA	0.58	0.66	0.92	1.00			
V3	0.55	0.64	0.91	0.98	1.00		
V2_AR	0.66	0.74	0.95	0.99	0.97	1.00	

Although V2 and V3 are highly correlated, their levels dimer, especially during the 10 ... rst years of the sample. Adding output to the system (V3) increases the NAIRU volatility and changes its reaction to shocks: for instance, during the early 1990s, when unemployment went above 11% (the immigration in tux from former Soviet Union countries was at its peak then), the augmented form (V3) reacts much more to changes in the actual rate (an 0.5 percentage point increase) while the reduced form (V2) indicates that the NAIRU hardly changed: this leads to a di¤erence of 0.8 percentage points between the two estimates during 1992. The reason may be that when taking information on output into account, the model "interprets" the output rise in 1991 as a permanent shock, i.e., as a rise in potential output; As a result, the NAIRU increases more dramatically (during this episode unemployment rised as well, without any downward pressure on prices, after controlling directly for immigration). The immigration shock caused a simultaneous rise in output and unemployment. It seams that the augmented model handles better the immigration shock, as the new immigrants increases permanently the labor force; It is reasonable to believe that this shock caused the NAIRU to increase for the short run.

Minor di¤erences between the versions are apparent after immigration has slowed down.

Figure 4: Potential output

4.2 The unemployment gap

The derived unemployment gap re‡ects the business cycle state. As such, the gap should follow some regularities, namely the persistence and stationary nature of the business cycle. The parameters of the transition matrix F of all estimated models point out that the unemployment gap follows a stationary process, although the parameters show that this is a borderline-case¹³. Note that the unemployment gap is modelled as an unrestricted AR(2) process. When checking the gap itself the results are inconclusive, however. An ADF test shows that the unit root hypothesis may be rejected based on high critical values only (i.e. the ADF test statistic is near the 5% critical value).

4.3 Potential output and the Output Gap

This section presents the potential output and imputed output gap derived from the 3rd version (AJ model). The estimated drift is 1.19, retecting a 4.76 annual growth rate. The system output is compared with both HP ...Itered series and a Kalman ...Iter series generated by the non-structural system of section 2.2.

The estimated output gap is highly correlated with the unemployment gap: this result is not surprising, as the output gap, by construction, is related to the unemployment gap only. Yet, the augmented system speci...es the potential

¹³Some of the eigenvalues of the transition matrix F equal one.

Figure 5: Output gap

output's stochastic process, and this leads to changes in the estimated NAIRU (V3 in ...gure 2).

Figure 5 presents the di¤erent output gaps derived from the augmented system (V3), the output gap derived from a pure statistical decomposition (KF), and the output gap as a di¤erence between actual and HP ...Itered output (HP). The main di¤erence that meets the eye is the "interpretation" of each method of the 1992 mass immigration period. The HP ...Iter gap indicates that this period was a business boom, while the State Space Model shows that potential output rose signi...cantly during this period, leading to the conclusion that this movement of output was not cyclical. The statistical decomposition (KF) lies in between: the interpretation is that this model better captures permanent shocks than a simple HP estimate. A closer look at the gaps reveals the following results: the correlation between HP and KF is 0.77, and the correlation between HP and V3 is 0.54; the ACF of HP gap indicates that only the ...rst two terms are signi...cant, while the ACF of the other methods contain 6-7 signi...cant terms. This implies that these methods comply with our perception of the "business cycle", while a simple HP gap does not exhibit a cycle at all.

4.4 Con...dence intervals

Being conditional expectations, estimated state variables have two sources of uncertainty. The ...rst, due to "parameter uncertainty", retects the uncertainty around the estimated parameters in H and F matrices. This type of uncertainty would remain even if the state variables were observed and model was estimated using standard regression methods. The second type of uncertainty is the "...Iter uncertainty" and retects the fact that the estimated Z -values represent conditional expectations of true unobserved values. This uncertainty is due to Kalman ...Iter estimation and would be present even if the true values of the matrices H and F were known. A decomposition of mean squared error P_{tjt} into these components is shown in Hamilton (1994, pp.397-399).

The question is what is the pivotal statistic that enables us to build the con...dence interval around the estimated state variables, taking into account both sources of uncertainty. Obviously, the use of a prediction interval in this case will overestimate the uncertainty since it relates to out-of-sample error terms.

In order to roughly estimate the con...dence interval around the unobserved

NAIRU we applied the jackknife technique ¹⁴. The idea of jackkni...ng is to modify the sample by randomly deleting one or a group of observations and to measure the generated bias in the statistic of interest. The bias measured by repeating this procedure, and normalized in a special way (see appendix D), should have an approximate t distribution, and constitutes a pivotal statistic for robust interval estimation (Miller (1974)).

This simulation enables us to get an idea of the aggregate uncertainty around the unobserved components directly, that is, without estimating each source separately.

During the last two decades the resampling techniques (rather bootstrapping than jackknife) were applied in a time-series domain for model selection [Veall (1992)], as well as parameters and standard error checks (see, for example, Li (1994), Sto¤er and Wall (1991), Brownstone (1990)).

Since our observations are serially correlated, instead of deleting the row of observations, we replaced it by the average of its neighbours. Such "interpolation" resembles row deleting because the modi...ed observation is not independent and does not contain any new information. The deleted rows were chosen by a random counter. After this treatment, we re-estimated the model. Thus, new estimates of the state variables were obtained, together with the new system matrices H and F. Repeated 22 times, this simulation created 22 versions of each state-variable for each date. The details about the data processing are given in appendix D. The outcome of this experiment is that the con...dence bands, computed by jackkni...ng, are much narrower than the prediction intervals by the Kalman ...Iter. Yet, the con...dence bands, obtained by jackkni...ng, contain both sources of uncertainty, as discussed before.

The ...gures below show the standard 95% con...dence band for the NAIRU for the three di¤erent models(V1, V2, V3). Model V3 was used to estimate the con...dence bands for Potential Output. As presented in the ...gure below, the uncertainty around the NAIRU estimates depends on the model that was used. Augmenting the model by new state variables increases the uncertainty around the NAIRU estimates.

¹⁴ We thank I. Muchnik for suggesting this strategy.

Figure 6: NAIRU con...dence bands

The conclusion from model V3 is that in the standard con...dence band, actual unemployment was signi...cantly di¤erent from the NAIRU only during three episodes. This re‡ects the limited power of the unobserved components approach. Similar results were reported by Laubach (2001), where for most countries that were checked, the unemployment rate from 1970 to 1998 varied within the 95% con...dence band¹⁵. This led Laubach to the conclusion that "The question whether at any point in time the actual unemployment rate is above or below the NAIRU can rarely be answered at conventional con...dence levels". Note that the parsimonious models V2 and V1 generate lower uncertainty around the estimated NAIRU. This result is straightforward, as augmenting the State Space representation by new unobserved components increases uncertainty.

The limited uncertainty regarding the NAIRU estimates are mirrored in the uncertainty around Potential Output estimates. Again, using the standard con...dence bands, actual output was signi...cantly di¤erent from potential output only during three episodes. The high growth rate during 2000 for example, is still in the con...dence band for potential output.

¹⁵ This referes to the Bivariate model with I(2) NAIRU, that seems to better capture the upward unemployment trend in the inspected countries. This model implies that the NAIRU was within the band throughout the period in Canada, France, Italy and Australia; while in Germany, the US and the UK it was signi...cantly di¤erent, at least once.

Figure 7: Potential output con...dence bands

4.5 Sample exects

Although the sample period that we used for estimation is relatively short, still, one could question our assumption that the links between the variables are constant, or technically, that the system matrices H and F are not time-varying.

The problem with this approach is that it is clear that during this period (1987-2001), some structural changes, especially in the labor market, took place. Since wage determination is one of the channels that the Phillips curve works through, these changes pose the question whether the exect of the unemployment gap on prices has changed.

On one hand, major changes in the labor market took place due to the mass immigration wave. This supply side shock reduced the bargaining power of workers both directly and indirectly, as the new workers, most of them unorganized, reduced the bargaining power of labor unions. On the other hand, the transfer payments policy became more generous, o¤setting the immigration wave e¤ect on the reservation wage, and leaving the total e¤ect on the NAIRU unknown.

In addition to these exects, the number of foreign workers increased dramatically during the 90's. Note that all these factors may axect the participation in labor force as well.

In order to answer these questions we also estimated the NAIRU for a sub sample starting on 1995 – a post mass immigration period. The results im-

Figure 8: The NAIRU: sample exect

ply that the total exect of unemployment gap on prices is similar, but the lag structure is dixerent: changes in intation are much more sensitive to contemporaneous unemployment gap, rather than to lagged gap as for the whole sample. This may be the result of a less rigid labor market.

The estimation results of the augmented system (V3) implies that the same holds for the Okun's law equation (12), where the link between unemployment and output gap becomes contemporaneous rather than lagged. Again, this may retect a more texible labor market in which changes in output are mirrored immediately in the unemployment rate.

Figure No.8 compares the NAIRU generated using the whole sample to the NAIRU as generated by the new, reduced, 1995-2001 sample. The results show that the NAIRU is stable with respect to sample exects. Note that the new sample is enlarged to end-2001 (three more observations compared to the full sample), this enables us to check the end-sample exect, therefore we check simultaneously for two dixerent sample exects. The end sample exect can be seen clearly after 1996, when the NAIRU's were almost identical. During 2001 the actual rate of unemployment increased steeply from 8.6 % at the ...rst quarter to 10.3 % at the last quarter. Since this process was not followed by acceleration downwards in the rate of in‡ation, the model interprets this as a rise in the NAIRU. Since we use smoothed Kalman estimates, which use the full information set, pre – 2001 NAIRU's are updated upwards (the "stickiness " of the NAIRU does note allow for dramatic jumps). This explains the growing dixerence between the estimates after 1996. Still, the dixerence between the estimates at the ...rst quarter of 2001 is less than 0.5 percentage points.

The sample exect on the output gap is more substantial. This is partly

Figure 9: The output gap: sample exect

because the output gap is not smooth as the NAIRU. Note that the di¤erences in the NAIRU (and hence in the unemployment gap) are not re‡ected in the output gap. For example, the output gap according to the di¤erent samples was identical during the third quarter in 2000, while the NAIRU was di¤erent. This is the result of the changing coe¢cients in the Okun's law equation (H matrix). Yet, the di¤erences between the estimates are not large: the largest di¤erence is between the gaps is near one percentage points (during 1996 peak).

4.6 Prediction

This section describes one-step-ahead predictions of the unobserved components. In order to generate these predictions, we used the whole sample to compute the system matrices (assuming that they are time-invariant), and then applied the prediction equation of the Kalman ...Iter (see appendix C) for each observation, starting from 1997:3. When comparing the predicted sub-series with previously computed expected (smoothed) values of state variables we found a very good ...t. The correlation between the predicted NAIRU and its smoothed "realization" is 0.8.

Figure 8 presents the predicted values of the unemployment gap and its "realisations" for the last four years of the sample. These results point out that the system is very stable, suggesting that it may be used for short-term prediction. Note that these results were achieved by using the same system matrices for the whole sample: obviously, updating the matrices at each step will improve the prediction power.

Figure 10: Prediction

5 Conclusions

The substantial changes of unemployment rates, in‡ation rates, and the labour market structure during the last decade, raise the question as to what extent these changes are re‡ected in the NAIRU. In order to answer this we constructed State Space Models in which the NAIRU and potential output are latent variables. These variables are identi...ed by both economic relations such as the Phillips curve and Okun's law, and by non-theoretical assumptions about their evolution over time. Following the state-of-the-art literature in this ...eld, we start by estimating the NAIRU only with the simple univariate model (V1) suggested by Gordon (1997), and a bivariate speci...cation (V2) as used by Laubach (2001). Next, we estimate a variant of the AJ model (1999), an augmented SSM for simultaneous estimation of the NAIRU and potential output (V3).

We use the Kalman ...Iter, combined with a quasi -maximum likelihood algorithm for restricted SSM estimation (EM) of Watson and Engle (1983), in order to estimate the model parameters (the system matrices), the unobserved components. In addition, we use the jackknife technique to quantify the uncertainty around these estimates – namely, the uncertainty around the NAIRU and potential output -due to the fact that these variables are unobserved, and that the system matrices are estimated and hence are not known without uncertainty. The fact that each model is completely nested in the next speci...cation allows us to shed some light on the trade-o¤ between the goodness-of-...t of the model and the uncertainty around the estimated unobserved components.

The estimation results suggest that the NAIRU path is relatively stable, with no clear evidence for hysteresis after the unemployment peak of 1991¹⁶. Note that this conclusion is based on models where the volatility of the NAIRU is not restricted; that is, this outcome is not a result of any direct restrictions on the NAIRU path, while the simple model (V1) required this restriction in order to reach convergence (as in Gordon (1997)). The estimated NAIRU during the sample period varied within approximately a one percentage point band, while the unemployment rate varied between 5.8 and 11.8 percent. The derived unemployment gap had a signi...cant negative exect on the price process, as presented in the single equation estimates of the Phillips curve. This in turn justi...es the use of such an equation as an identifying equation, as it contains signi...cant information about the unobserved components. As always, using the state-space methodology does not come without a cost: the uncertainty around the unobserved components is substantial, and therefore, usually, it is hard to judge the state of the economy using the conventional con...dence levels, as for example holds for the period 1997-2001. This leads to the conclusion that one should use caution when deriving direct policy implications based on the NAIRU estimates.

A Data

This section describes variables used to estimate the quarterly model for Israel from 1987:1 to 2001:4.

Endogenous observed variables:

(y) - Gross Domestic Product, at ...xed 1995 prices, reported quarterly by CBS, seasonally adjusted by X12 procedure, levels at natural logarithms.

(\protect pai) - consumer price index, reported monthly by CBS, seasonally adjusted and log dimerenced at quarterly level. This variable is called pai. The variable used in the model is \protect pai, that is ...rst dimerence of pai multiplied by 100.

(u) - chained unemployment rate (%), reported quarterly by CBS, seasonally adjusted.

Exogenous variables:

(rer) - Real Exchange Rate of Israel, reported quarterly by IFS statistics (IMF), log di μ erence.

(mp) - import \$ price index, excluding fuel and diamonds, PASH formula, reported quarterly by CBS on 1991 base, seasonally adjusted and log di erenced.

(productivity) – labor productivity, measured as the relation of GDP to the number of employees (natural logarithm of this relation is used). Employees include Israelis, Palestinians and foreign workers. Israeli employees data, based

¹⁶ At least as retected in the unemployment rate. The estimates show that the disintation process during the 1990s did not cause an increase in the NAIRU. Nevertheless, it is possible that hysteresis a¤ected the participation-in -labor-force rates.

on Labour Force surveys, have been chained through their multiple samples. GDP and employees time-series are seasonally adjusted.

(oil) – fuel import price index, PASH formula, reported quarterly by CBS on 1991 base, log di¤erenced. No seasonality was found.

(rel_mp) – relative import price (excluding fuel and diamonds), computed as import NIS price index relatively to CPI. To convert \$ price index into NIS, representative exchange rate is used. CPI and import price indices are seasonally adjusted. The log di¤erences of their relations are used.

(rel_delek) – relative fuel import price computed as import NIS fuel price index relatively to CPI. To convert \$ fuel price index into NIS, the average exchange rate is used. The CPI quarterly index is seasonally adjusted. Log di¤erence of this index is used.

(immigration) – the share of new immigrants in population growth. Measured as quarterly new immigrant arrivals relative to total population growth. The ...rst di¤erence of this relation is used.

All quarterly time-series are supported and currently updated by the Bank of Israel Research Department Database.

B Systems

This section describes all the State Space systems that were estimated.

All the Moving Average systems take the same set of exogenous variables. The Auto Regressive systems take the same set plus four lags of C_{4} .

All exogenous variables are normalised to zero.

B.1 Version 1

Measurement

B.2 Version 2 (AR)

Note that there is no explicit error term in the measurement equation. The implicit error term " $_{\rm t}$ is a state variable.

B.4 Version 3

M easurement

implicit error term " $_{t}$ is a state variable.

C The Kalman ... Iter and Smoother

The SSM (or SSF - State Space Form) allows us to distinguish between two blocks of equations: the measurement/signal block describes the dependence of observed components (such as intation and output) in a set of variables, of which some may be unobserved, and others observed exogenous variables. This block may be based on theoretical grounds (hence, "structural"), or on identities (see appendix B). The second block, the transition/state block describes the stochastic process of the unobserved components. This block contains atheoretical assumptions describing the way the unobservables evolve over time. Though some of these assumptions may be justi...ed empirically, such as the evolution of potential output that is proxied by a random walk plus drift process, these assumptions retect the fact that our knowledge about these unobservables is limited (AJ, (1999)).

The SSF is composed of two equations. The measurement (or observation) equation relates $n \pm 1$ vector of observable variables y_t , to $^{(8)}_t$, an $m \pm 1$ vector of unobservable variables (the state vector).

$$y_t = Hz_t + BX_t + "_t$$
 (18)

where H is an n £ m matrix, and "t is an n £ 1 vector of serially uncorrelated disturbances, satisfying $E("_t) = 0$ and $Var("_t) = O_t$. The elements of ® are unobserved. X is a matrix of observed exogenous variables.

The transition (or state) equation speci...es the stochastic process generating the unobservable ®'s as a ...rst order Markov process

$$z_t = F z_{t_i 1} + R'_t$$
(19)

Where F is an m £ m transition matrix. $E(_t) = 0$ and $Var(_t) = Q_t$: The matrices H; X; Q; F; R will be referred to as the system matrices. The models that are estimated in this study assume that the system matrices do not change over time. Hence, the system is time-invariant, and the time subscripts may be omitted from the system matrices.

The assumptions below complete the speci...cation of the state space system: $E(^{\textcircled{B}_0}) = a_0 \quad V \mbox{ ar}(^{\textcircled{B}_0}) = P_0$ where $^{\textcircled{B}_0}$ is the initial state vector. and P_0 is the initial state variance.

The disturbances of the measurement and transition equations are assumed to be uncorrelated with each other in all time periods, and uncorrelated with the initial state $@_0$:

Once rewritten in a state space form, the system may be estimated, including the unknown parameters, using the Kalman Filter and smoother. The Kalman Filter is a recursive procedure for computing the optimal estimator (thus, minimising the Mean Square Error) at time t based on the information available at that time. This information consists of the observations up to and including $y_t. \ensuremath{\text{The}}$...Iter consists of two sets of equations: the ...rst set is the prediction equations that generate optimal predictors for the state vector z_t , based on the information set at t $_i\,$ 1. Let $a_{t_i\,$ 1 be an MSE of the state vector $^{\circledast}{}_{t_i\,}{}_{1_i'}$ and $\mathsf{P}_{t_i\,}{}_1$ be the m £ m covariance matrix, $P_{t_i 1} = E(a_{t_i 1 j} \ {}^{e}_{t_i 1})(a_{t_i 1 j} \ {}^{e}_{t_i 1})^{'}$, based on the information at $t_i 1$, thus based on $y_{t_i 1}$. Then the prediction equations are simply given by $a_{t=t_i 1} = Fa_{t_i 1}$ and $P_{t=t_i 1} = FP_{t_i 1}F'' + RQR'$. Once a new observation y_t is available, it is possible to update the estimated state vector $a_{t=t_{\mbox{\scriptsize i}}\mbox{\scriptsize 1}}$ and its covariance matrix $P_{t=t_{\mbox{\scriptsize i}}\mbox{\scriptsize 1}}$ using the information embodied in the prediction error: $e_t = y_t i Ha_{t=t_i 1 i} SX_t$. This is done by the updating equations $a_t = a_{t=t_i 1} + P_{t=t_i 1}HF^{i 1}e_t$ and $P_t = P_{t=t_i 1 i} P_{t=t_i 1}HF^{i 1}HP_{t=t_i 1}$ where $F = HP_{t=t_{i-1}}H^{0} + Q$. The estimators for a_t and P_t that are generated using the updating equations are called ... Itered estimates. Note that these estimates are based on the information set up to and including y_t only, thus, the ... Itered estimates were generated using a one-side ...Iter (unlike moving average ...Iters, for example). As pointed out by Harvey (1989) and Hamilton (1994), when the state variable of interest has some economic meaning, it is better to use a full information set: thus, in order to estimate the NAIRU at time t, where t = 1::T it is better to use the information up to T - NAIRU_{t=T}, than using the truncated information set $NAIRU_{t=t}$. Thus, after the ...Itered estimates for the whole sample are computed, we use the Kalman smoother to generate full information set estimates. The smoothed estimates are generated using the backward recursion: $a_{t=T} = a_t + P_t^{\pi}(a_{t+1=T} \mid Fa_t)$, and $P_t^{\pi} = P_t F P_{t+1=t}^{i 1}$

D Jackknife technique

Let Z_{k}^{j} be the i-th observation of the k-th state variable (.i.e. NAIRU), obtained as result of the estimation procedure on the whole sample of size T (in our case T=57 quarters). This value constitutes a conditional expectation of the true value Z_{k} .

of the true value $Z_{k,i}$. Let \mathbf{Q}_{i} be the corresponding observation, estimated on the "spoiled" sample, when the i-th original row of data (dependent and independent variables relating to the i-th date) was deleted and substituted by averaging the neighbours around it. Suppose this procedure was repeated g times.

Consider all multiple realisations of the k-th state variable at date $\ensuremath{\boldsymbol{\imath}}$ and de...ne:

$$\mathbf{Z}\mathbf{Q}_{i}^{(i)} = \mathbf{g}\mathbf{Z}\mathbf{Q}_{i}^{(i)} (\mathbf{g}_{i} \mathbf{1})\mathbf{Z}\mathbf{Q}_{i}^{(i)}$$

and

$$\mathbf{Z}\mathbf{Q}_{\dot{c}} = \frac{1}{g} \mathbf{X}_{i=1} \mathbf{Z}\mathbf{Q}_{\dot{c}}^{(i)}$$

The length of the con...dence interval $j \mathbf{A}_{i} \mathbf{Z}_{k} \mathbf{z}_{j}$ for the f_{i} ; kg observation may be found as:

$$t_{\text{@;g_i 1}} \underbrace{\underbrace{\mathbf{F}}_{i=1}^{\mathbf{F}} (\mathbf{Z}_{i}^{\text{(i)}} | \mathbf{Z}_{i}^{\text{(i)}})^{2}}_{g(g_{i} 1)}$$

where $t_{@:g_{i-1}}$ is taken from the Student distribution with @ and (g_{i-1}) degrees of freedom (see Miller, (1974)).
